Revised 3 Oct 2018

Key Points:

• Rain layers were detected at values of $U_{10}$ up to 9.8 m s$^{-1}$ while diurnal warm layers were only detected at $U_{10} < 7.6$ m s$^{-1}$ (99th percentile values)

• The formation and persistence of stable layers at depths ≤ 5 m were well-estimated by $U_{10}$ and the surface buoyancy flux, $B$

• Rain layers (and their combinations with diurnal warm layers) formed often in disturbed and active MJO periods before westerly wind bursts

ABSTRACT

Stratification of the upper few meters of the ocean limits the penetration depth of wind mixing and the vertical distribution of atmospheric fluxes. Significant density stratification at depths ≤ 5 m was observed in 38% of a two-month dataset from the central Indian Ocean collected during DYNAMO. Diurnal warm layers (DWLs) formed by solar heating populated 30% of the dataset and rain layers (RLs) populated 16%. Combined contributions from rain and insolation formed RL-DWLs in 9% of the dataset. RLs were detected at values of $U_{10}$ up to 9.8 m s$^{-1}$ while DWLs were only detected at $U_{10} < 7.6$ m s$^{-1}$ (99th percentile values), symptomatic of the greater buoyancy flux provided by moderate-high rain rate compared to insolation.

From the ocean friction velocity, $u_w^*$, and surface buoyancy flux, $B$, we derived estimates of $\hat{h}_S$, stable layer depth, and $\bar{U}_S$, the maximum $U_{10}$ for which stratification should persist at $\hat{h}_S$ for fixed $B$. These estimates predicted:

1) 36 out of 44 observed stratification events (88% success rate),
2) the wind limits of these events.

This suggests a means to determine the presence of ocean stable layers at depths ≤ 5 m from $U_{10}$ and $B$.

Near-surface stratification varied throughout two Madden-Julian Oscillation (MJO) cycles. In suppressed MJO periods, ($U_{10} \leq 8$ m s$^{-1}$ with strong insolation), RLs and RL-DWLs were rare while DWLs occurred daily. During disturbed and active MJO periods, ($U_{10} \leq 8$ m s$^{-1}$ with increased rain and cloudiness), multiple RLs and RL-DWLs formed per day and DWLs became less common. When westerly wind bursts occurred, ($U_{10} = 7$-17 m s$^{-1}$ with steady rain), RLs formed infrequently and DWLs were not detected.
Plain Language Summary

We found that rainfall and clear skies often led to stabilization of the upper 5 m of the central Indian Ocean, except during strong winds. Near-surface stable layers impact the density and mixing of the ocean because rain water and near-surface water heated by the sun are lighter than typical ocean water, which is relatively cooler and saltier. Stable layers are important to understand because they influence sea surface temperature and ocean heat content, which impact weather and climate. Compared to previous studies, we more precisely determined the wind speed below which stable layers form and above which they do not. This will hopefully aid researchers and forecasters tasked with predicting tropical weather, climate, and ocean processes.

Prior to this study, it was unclear how often ocean stable layers formed during each phase of the MJO, a major tropical phenomenon that impacts weather and climate around the world. We found that rain layers (and their combinations with diurnal warm layers) occurred most often during disturbed and active MJO periods prior to wind bursts. Diurnal warm layers tended to form in earlier stages of the MJO, in its suppressed and disturbed periods.
1. Background and Motivation

Near-surface ocean stabilization can be achieved by either heat or freshwater inputs, which suppress subsurface mixing and confine subsequent surface inputs of heat, momentum, and freshwater to a shallow near-surface layer (Miller 1976, Price 1979, You 1995, Soloviev and Vershinsky 1982, Fairall et al. 1996a, Soloviev and Lukas 1996, 1997, 2006, Anderson et al. 1996, Smyth et al. 1996a, b, Wijesekera and Gregg 1996, Wijesekera et al. 1999, Asher et al. 2014, Drushka et al. 2016). Near-surface stable layers can in turn impact sea surface temperature and salinity (SST, SSS). Thermal stratification produces diurnal warm layers (DWLs) and freshwater stratification produces rain layers (RLs). RLs occur often in tropical oceans where precipitation is high and wind speeds are relatively low (Lukas and Lindstrom 1991, Drushka et al. 2016). However, the wind limits on RLs and the prevalence of RLs throughout the lifecycle of the Madden-Julian Oscillation (MJO) are unreported. On 30- to 60-day time scales, the MJO explains the majority of variance in tropical net heat flux, wind, sea surface temperature (SST), and rainfall (Zhang 2005, Lau and Waliser 2005, de Szoeke et al. 2014, DeMott et al. 2015). In contrast to RLs, numerous previous studies report on DWL persistence and DWL occurrence relative to MJO phase (Price et al. 1986, Webster et al. 1996, Soloviev and Lukas 2006, Kawai and Wada 2007, Bellenger and Duvel 2009, Matthews et al. 2014, Asher et al. 2014). DWLs form in response to absorption of shortwave solar radiation within the upper few meters of the ocean. They have been observed when the 10-m level reference wind speed corrected for neutrally-buoyant conditions, $U_{10}, \leq 7$ m s$^{-1}$. The suppressed MJO period is characterized by conditions of strong solar insolation and low wind speed, so DWLs are frequently observed to form during this time. Unlike DWLs, the degree to which RLs and RL-DWL combinations can

Understanding the role of wind-forced mixing in the formation and evolution of RLs, DWLs, and RL-DWL combinations is important for predicting SST. When DWLs and RLs are present, surface inputs of momentum, heat, and freshwater are confined to shallow near-surface layers. Daytime SST anomalies in DWLs can reach at least 4°C according to previous studies (Fairall et al. 1996a, Soloviev and Lukas 1997, Wijesekera et al. 1999, Woolnough et al. 2000, Lau and Waliser 2005, Ward 2006, Drushka et al. 2012, Matthews et al. 2014, Soloviev and Lukas 2006, Bellenger and Duvel 2009, Reverdin et al. 2012, Seo et al. 2014, DeMott et al. 2015). In comparison, the intraseasonal variation in daily-mean SST is typically only 1°C (Lau and Waliser 2005, Demott et al. 2015).

Due to the impact of SST on atmospheric convection, both free-running and hindcast general circulation models produce improved MJO simulations when air-sea coupling is included

Parameterizations of ocean surface stratification by rain and diurnal warming are necessary in coupled models concerned with accurate prediction of SSS and SST. DWL parameterizations and 1-D ocean mixing models can reproduce observations of ocean thermohaline structure when horizontal advection, underlying barrier layers, and other vertical processes are not dominant factors (Price et al. 1986, Fairall et al. 1996a). For example, the Rain Impact Model (RIM) provides a macro (i.e. 100 km) scale parameterization of rain’s impact on the ocean. However, RIM still requires testing with finer-scale observations of in-situ $U_{10}$ and rain rate, $R$ (Santos-Garcia et al. 2014) and so far does not include DWLs.

Despite the importance of stably-stratified surface layers in controlling SST, near-surface ocean stratification is not routinely observed. Owing to their shallow depth (typically less than a few meters), DWLs and RLs are not detected by moorings without sensors in the upper 2 meters (Prytherch et al. 2013). Similarly, Argo floats, expendable bathythermograph (XBT), and many ship-based measurements often do not provide data within the first few meters of the ocean surface and provide limited temporal and spatial coverage (Anderson and Riser 2014, Chi et al. 2014, Asher et al. 2014). Therefore, mixed layer depth climatologies developed using these data describe the regional, monthly, nighttime, or daily-mean mixed layer depth, which is typically 10-30 m in the central Indian Ocean and varies by ±15 m throughout an MJO cycle (de Boyer Montegut 2004, Schmidthk et al. 2013, Drushka et al. 2012, DeMott et al. 2015, Holte et al. 2016).
Climatologies developed using Argo data focus on mixed layer depth variability over time scales on the order of one to two days since Argo data do not sample fast enough nor with sufficient vertical resolution near the sea surface to resolve diurnal or sub-diurnal processes in the upper 10 m.

Both Argo profiles and satellite overpasses are too infrequent relative to rain events to characterize the occurrence rate of RLs and RL-DWLs, or to determine their sensitivity to $U_{10}$. To some extent, the presence of RLs and DWLs can be detected by comparing the upper-most Argo or mooring measurements of S and T with satellite-derived SSS or SST (Kawai and Wada 2007, Boutin et al. 2013, Anderson and Riser 2014, Drushka et al. 2016). However, scatterometer- and radiometer-based measurements of $U_{10}$, SSS, and SST are contaminated by precipitation and their 25-100 km scale footprints can also be too coarse spatially and temporally (e.g. updating only a few times per day) to resolve the atmospheric mesoscale footprint of rain (Kummerow 2003, Kilpatrick et al. 2015).

Ship observations have detected stable near-surface salinity gradients generated by rain for a range of rain rates so long as $U_{10} < 9.5 \text{ m s}^{-1}$ (You 1995, Soloviev and Lukas 1997, Anderson et al. 1996, Smyth et al. 1996a, b, Wijesekera and Gregg 1996, Wijesekera et al. 1999, Cronin and McPhaden 1999, Asher et al. 2014). In contrast, observations during tropical storms ($U_{10} \geq 18 \text{ m s}^{-1}$) and hurricanes ($U_{10} \geq 33 \text{ m s}^{-1}$) do not show the presence of stably-stratified RLs (D’Asaro et al. 2012, Jourdain et al. 2015). From these previous studies, it remains unclear whether 9.5 m s$^{-1}$ represents the upper limit of $U_{10}$ at which a RL can form, and if indeed this value is an upper limit, why that should be the case. According to these previous studies based on field measurements, understanding the formation and evolution of RLs, including the effect of wind speed on their lifetime, is complicated by several factors:
• in addition to local rain, freshwater from nearby rain can be advected by the current into ocean sensors;

• RLs spread and propagate laterally like density currents (Soloviev et al. 2015);

• RL creation and longevity depend on upper ocean turbulence, waves, and wind mixing.

These factors explain why RL observations are not always highly-correlated to their generating rain events and why RL detection is not guaranteed from every rain event even if near-surface salinity measurements are available, as noted by You (1995). Observations (Asher et al. 2014) and model results (Drushka et al. 2016) suggest that shallow, stable near-surface vertical salinity gradients generated by rain form primarily when the rain rate, $R \geq 5 \text{ mm h}^{-1}$. For tropical ocean conditions, the buoyancy produced by $R = 5 \text{ mm h}^{-1}$ is equal and opposite to the buoyancy destroyed by a surface cooling on the order of $Q_{\text{Net}} = 400 \text{ W m}^{-2}$ (demonstrated in Appendix A, also see Dorrestein 1979). Additional turbulence may also be provided by wind, waves, or subsurface shear. Thus, when $R < 5 \text{ mm h}^{-1}$, the freshwater from rain tends to be mixed into the water column by a combination of surface cooling and turbulent mixing so that a stratified surface fresh layer does not form. Miller (1976) also modeled RLs, noting that initializing light rain rates with strong winds (45 mm accumulation over 15 h while $U_{10} = 10 \text{ m s}^{-1}$) resulted in the formation of a mixed layer that was 38-m deep with no detectable SSS or SST change. This showed that the rain was mixed downward and formed a homogeneous layer. When high rain rates were modeled with low wind speeds (45 mm accumulation over 4 h while $U_{10} = 5 \text{ m s}^{-1}$), a RL formed at 0.76 m depth and the greatest changes in SST and SSS were observed.

Our current understanding of RLs motivates the following questions:

a) What is the maximum $U_{10}$ under which a RL or RL-DWL can form and persist?

b) Is this upper limit of $U_{10}$ a function of $R$?
c) How often do RLs and RL-DWL combinations occur throughout the suppressed, disturbed, active, and westerly wind burst (WWB) periods of the MJO?

The ocean surface buoyancy flux and the turbulent kinetic energy (TKE) input to the ocean provided by wind are both functions of MJO phase (e.g. Zhang 2005, Moum et al. 2014). This should impact the formation and persistence of surface stratification throughout the MJO lifecycle. The penetration depth of wind mixing into the ocean is determined by a balance between stabilizing buoyancy forces and TKE production as given by Monin-Obukhov theory (Lombardo and Gregg 1989, Brainerd and Gregg 1995, 1997, Price et al. 1986). This theory suggests that a near-surface stable layer can persist during high wind speeds provided the stabilizing buoyancy flux is large enough. If this hypothesis is true, then RL and RL-DWL formation should be most likely in disturbed and active MJO periods when high rain rates occur, even though surface wind speed may be great at times (e.g. Zhang 2005, de Szoekoe et al. 2014, 2017). In the western Pacific warm pool, RL formation was observed during a WWB with prolonged rain and $U_{10} = 9.5 \text{ m s}^{-1}$ (Wijesekera et al. 1999). This indicates that RL formation is possible during WWBs despite strong winds. In contrast to RLs, DWLs have typically only been observed during the suppressed phase of the MJO and when $U_{10} \leq 6-7 \text{ m s}^{-1}$ (Webster et al. 1996, Bellenger and Duval 2009, Matthews et al. 2014). As will be shown in this study, the buoyancy created by rain is typically an order of magnitude greater than that due to maximum net surface heating. Therefore, it stands to reason that RLs should form and persist at higher $U_{10}$ than DWLs, and RLs should also occur in disturbed and active stages of the MJO, after the suppressed MJO period that is characterized by frequent DWLs.

This study makes use of ship-based surface observations, including measurements of air-sea fluxes, radar-observed rain, and in situ vertical profiles of ocean salinity and temperature.
These data are used to better understand how wind stress interacts with the buoyancy flux in the formation and evolution of DWLs, RLs, and RL-DWLs observed throughout the MJO lifecycle. These data were collected in the central Indian Ocean throughout the two MJO cycles observed during the 2011 Dynamics of the MJO (DYNAMO) experiment (Johnson and Ciesielski 2013, Yoneyama et al. 2013, Moum et al. 2014). A method is developed for identifying the presence of a near-surface ocean stable layer. This method is used to track ocean stratification from the combined effects of diurnal warming and rain and to explore the sensitivity of stable layer formation and persistence to $U_{10}$. Observations are compared to estimates of stable layer depth and stable layer wind limits that were derived from Monin-Obukhov similarity theory.

2. Observations and Analysis Methods

a. Field program and MJO time periods

Here we examine 42 days of DYNAMO observations made from the research vessel (R/V) Roger Revelle at 0°N and 80.5°E (Johnson and Ciesielski 2013, Yoneyama et al. 2013, Moum et al. 2014). We examined times when precipitation radar, upper ocean, and surface data were all available: from 5 Oct – 28 Oct and 12 Nov – 2 Dec 2011. These two time periods are separated by a 15-day restaffing, refueling, and transit period. Four time periods of the MJO were identified for this study region using the Real-time Multivariate MJO (RMM) Index (Table 1, http://monitor.cicsnc.org/mjo/current/rmm/). The RMM Index describes MJO conditions by combining tropical atmospheric measurements of outgoing longwave radiation (i.e. cloudiness) and zonal winds at 850 and 200 mb (Wheeler and Hendon 2004). Previous studies have used the RMM Index for guidance in describing the state of the MJO (e.g. Zhang 2005, Lau and Waliser 2005, Johnson and Ciesielski 2013, Gottschalck...
Phases 4, 5, 6, and 7 of the RMM Index were not well-observed in the central equatorial Indian Ocean during DYNAMO. We concentrate here on four specific periods, described in terms of atmospheric forcing conditions as suppressed (RMM phases 7-8), disturbed (phase 1), active (phases 2-3) and westerly wind burst (WWB, representing phase 3 when $U_{10} > 7$ m s$^{-1}$ for at least one day; wind criterion defined by Harrison and Vecchi, 1997). Statistics associated with each of these four periods are documented in Table 1. These time periods were used by Pujiana et al. (2018). The 42 total observation days in this study are made up of 14, 12, 10, and 6 days in the suppressed, disturbed, active, and WWB periods (Table 1).

In the central Indian Ocean, the suppressed MJO period is observed during RMM phases 5, 6, 7, and 8. Excluding the beginning of phase 5, these days typically have weak winds along with infrequent clouds and rain. DYNAMO days with upper ocean observations did not coincide with phases 5-6, so suppressed MJO days in this study only spanned phases 7-8. In November 2011, phase 7 only lasted three total days and observations were only collected on the last day; however, observations were collected during all four days of phase 8 in this month. In October 2011, data were collected on all ten days of phases 7-8. The suppressed period in this study is identical to that defined by Ruppert and Johnson (2015, 2016) and to the “undisturbed period” used by Johnson and Ciesielski (2017).

During the disturbed MJO period (RMM phase 1), clouds and precipitation become more frequent, more intense, and more expansive in terms of area (e.g. Riley et al. 2011, Xu and Rutledge 2014). The disturbed period begins on the day when the RMM index first equals 1; this day is regarded as the onset of the MJO by Ruppert and Johnson (2015, 2016) and Johnson and Ciesielski (2017). These previous studies define a disturbed period that spans all days following
the onset of the MJO, so the beginning of the disturbed period is the same in these studies and the current study. DYNAMO observations were made on all twelve days of RMM phase 1 that occurred over both months.

On active MJO days (RMM phases 2, 3), rain and clouds persisted throughout a majority of the daytime and nighttime hours, values of 24-hour rain accumulation and precipitation size reached maximum values, and stratiform rain contributed greatly to total rain amounts (determined with shipborne radar data by Xu and Rutledge 2015). All ten days of these active MJO conditions were observed during DYNAMO.

According to the definition by Harrison and Vecchi (1997), the WWB time period occurred in the DYNAMO study region on days when the RMM Index was 3-4 and when $U_{10} > 7$ m s$^{-1}$ for more than one day. During this period, rain was widespread, long-lasting, and made up of both convective and stratiform components, (e.g. Moun et al. 2014 and Xu and Rutledge 2015). DYNAMO ocean observations were not collected during phase 4, but one and five days of WWB conditions in phase 3 were observed in October and November, respectively.

b. Surface meteorology and air-sea fluxes

Near-surface meteorology (air temperature, specific humidity, and wind speed/direction at nominally 10-m above the sea surface) and air-sea flux estimates are at [ftp://dynamo.dms.uconn.edu/](ftp://dynamo.dms.uconn.edu/) linked by the Earth Observing Laboratory (EOL) field catalog: [http://data.eol.ucar.edu/master_list/?project=DYNAMO](http://data.eol.ucar.edu/master_list/?project=DYNAMO). Air-sea fluxes were computed using the COARE 3.5 bulk aerodynamic algorithm (Fairall et al. 1996b, Fairall et al. 2003, Edson et al. 2013, see complete description in de Szoeke et al. 2014). These data are available at 1- and 10-minute resolution. The 10-minute flux and surface data were utilized to match 10-minute resolution precipitation radar data and interpolated ocean data. A 10-minute resolution time
series of $R$ from the ship was acquired by resampling the 1-minute instantaneous $R$ data from ship gauges without performing any temporal smoothing. The net heat flux, $Q_{\text{Net}}$, was defined negative downward into the ocean (heating the ocean) and positive upward out of the ocean (cooling the ocean).

c. Precipitation

NASA TOGA C-band Doppler data from the R/V Revelle are also found on the EOL field catalog (http://data.eol.ucar.edu/master_list/?project=DYNAMO). These were quality-controlled to remove second trip echo and sea clutter and to correct for attenuation (details in Xu and Rutledge 2014). Polar-coordinate data were gridded using RadX2Grid, provided by the National Center for Atmospheric Research (https://www.ral.ucar.edu/projects/titan/docs/radial_formats/radx.html), to a 0.5 km horizontal, 0.75 km vertical Cartesian grid within 25 km range of the ship. Coarser 2 km horizontal resolution gridded data were also investigated out to the full range of the radar, 150 km, but are not presented herein. Radar data were at 10-minute resolution. The radar’s “cone of silence” limited the first usable radar data to 2 km range. Radar reflectivity, $Z_h$, was partitioned into convective and stratiform rain areas using the algorithm by Yuter and Houze (1998). Then $R$ was estimated in each area with either a convective or stratiform equation for $R(Z_h)$, which were fit to account for tropical oceanic rain variability by Thompson et al. (2015). Separate convective and stratiform $R(Z_h)$ equations help reduce error in $R$ estimation compared to treating the entire $Z_h$ field with a single $R(Z_h)$ equation fit to all data (Thompson et al. 2015). More details about these radar data procedures are in Appendix B.

Radar data were queried to identify times when precipitation existed upstream of the research ship. The research ship was always directed westward into the eastward-flowing surface
current, which was typically $0.8 \text{ m s}^{-1}$. A rain sector area was defined to extend 9 km from the ship in the upstream direction, between 235-300°, and to extend 4 km away from the ship in all other directions (Fig. 1, 104 km$^2$ total sector area). Sector extensions of 9 and 15 km were tested, which corresponded to advective time scales of about 3 h and 4.5 h from the upstream edge of the sector to the ship. Upper ocean evolution related better to rain within the sector that extended only 9 km upstream, so this extension distance was chosen for the rest of this study.

Values of $R$ from the ship radar’s rain sector and from the ship’s gauge were combined to form a 10-minute resolution time series of $R_{\text{MAX}}$, the maximum $R$ sampled from either the ship gauge or within the radar sector. Using this time series of $R_{\text{MAX}}$, 119 periods of rain were identified over the course of 42 intensive observation days. In order to qualify as a new rain event, rain was required to have not occurred for the previous 30 minutes. Rain event classification did not involve a minimum duration threshold, so the shortest rain event was the same resolution as the dataset, 10 minutes.

d. Ocean T and S

SST and bulk near-surface values of temperature, T, and salinity, S, were provided in the flux dataset discussed in Sec. 2b. SST was measured at roughly 0.05 m depth by a towed thermistor contained within a brass body that was sealed inside a floating Tygon tube, i.e. inside a sea snake (Fairall et al. 1997). Bulk T and S were measured by the ship’s thermosalinograph (TSG) using an intake at 5 m depth at the bow of the ship. The Chameleon profiler (Moum et al. 1995) was deployed from the stern of the ship and provided vertical profiles of S and T at 7-minute intervals with 1-m vertical resolution between 350 m depth and the sea surface depending on waves and swell. These data were mixed by the ship’s wake, so useful measurements began at 2-3 m depth. Ten thermistors sampling T at least 20 times per minute were also tethered along a
chain at a distance of 5 m away from the starboard bow. The thermistors were unequally spaced between depths of 1.5 m ≤ z ≤ 7.5 m along the chain (z is the vertical coordinate, z > 0 downwards). The vertical positions of the thermistors varied by approximately 0.5-1.0 m depending on the speed of the ship, the surface current, and surface gravity waves. These data were interpolated to a 1-m vertical grid. When the ship was headed into a steady mean eastward surface current, the thermistor chain provided a record of T measurements undisturbed by the ship’s wake (Moulin et al. 2018). In comparison, Chameleon profiling from the stern as the ship remained stationary and pointed into the steady eastward current. This approach yielded vertical profiles of T and S that were disturbed by the ship’s propulsion system over z < 7 m (the draft of Revelle is 5 m). In order to assemble vertical profiles of T and S that were most representative of open-ocean conditions, sea snake SST data and thermistor chain T data were used at z < 5 m, thermistor chain and Chameleon T data were averaged at z = 5 m and z = 6 m, and Chameleon T data were used at z > 7 m. Chameleon profiles provided the shallowest and most temporally continuous set of S measurements, which were used exclusively for S vertical profiles in this study. These vertical profiles of ocean T and S were resampled to the 10-minute interval of radar and flux datasets without performing any temporal smoothing, i.e. data points closest in time to the 10-minute interval were used.

**e. Ocean stability**

Vertical T and S gradients were used to calculate $N^2$, the Brünt-Vaisala frequency. The value of $N$ is a measure of static stability and relates to the natural frequency of internal gravity waves:

$$N^2 = \frac{g}{\sigma} \frac{d\sigma}{dz}$$  [1]
where $\sigma$ is the sea water potential density. The value of $N^2$ is positive for a statically-stable layer of water and negative for unstable conditions that are prone to convective overturning and vertical mixing. The linear approximation of the equation of state of seawater leads to an $N^2$ expression that can be scaled by the individual effects of $S$ and $T$ on $\sigma$:

$$N^2 \cong N_{S+T}^2 \cong N_T^2 + N_S^2$$ [2]

$$N_T^2 = g\alpha \frac{dT}{dz}$$ [3]

$$N_S^2 = g\beta \frac{dS}{dz}$$ [4]

where $\alpha [^{°C}^{-1}]$ is the thermal expansion coefficient of seawater:

$$\alpha = -\frac{1}{\sigma} \frac{\partial \sigma}{\partial T}$$ [5]

and $\beta [\text{PSU}^{-1}]$ is the salt contraction coefficient of seawater:

$$\beta = \frac{1}{\sigma} \frac{\partial \sigma}{\partial S}$$ [6]

Signs in [5] and [6] reflect that density increases as water becomes colder and saltier, such that [3] and [4] describe how the water column becomes more stable when a lighter fluid sits atop a denser fluid. The $\alpha$ and $\beta$ coefficients were calculated using the Gibbs-SeaWater (GSW) Oceanographic Toolbox (McDougall and Barker 2011) for each time and depth pair of $S$ and $T$ measurements during DYNAMO. Then, $N_S^2$ and $N_T^2$ were calculated between each vertical level at each time interval using estimated $\alpha$ and $\beta$ and the measured vertical $S$ and $T$ gradients. Fields of $N^2$ were smoothed with a 3-m vertical running mean filter with 1-1-1 weighting. Vertical profiles of $N_{S+T}^2$ calculated with [2] were nearly equivalent to vertical profiles of $N^2$ calculated directly from the vertical density gradient in [1]. Therefore, $N_{S+T}^2$ from [2] is used throughout this study and is abbreviated henceforth as $N^2$. Estimates of $N_S^2$ were available starting at 2-3 m,
while estimates of $N_T^2$ were available from 0-350 m. Therefore, $N^2$ was determined solely by $N_T^2$ where $z < 2$ m.

**f. Ocean stable layer identification algorithm**

Depth ranges were considered well-mixed if $4.5 \times 10^{-5} < N^2 < 4.5 \times 10^{-5} \text{ s}^{-2}$ over at least 3 consecutive meters vertically. Water was considered stable if $N^2 > 4.5 \times 10^{-5} \text{ s}^{-2}$ for at least 2 consecutive meters vertically. Using these definitions, an algorithm was devised to search for the top of the shallowest stable level in the ocean column, $h_S$, at 10-minute intervals. The algorithm also determined the base of the shallowest stable layer, $h_B$. Stable layers were required to be at least 2-m in vertical thickness in this study because data with 1-m vertical resolution were used. Therefore, the minimum stable layer thickness in this study was 2 m (i.e. $h_B - h_S \geq 2$ m). The minimum depth of $h_S$ was 0 m. The top depth of the thermocline, $h_{TC}$, was defined as the first level over which $N^2 > 1.75 \times 10^{-4} \text{ s}^{-2}$ for at least 3 consecutive meters. If the algorithm could not identify a stable layer shallower than 45 m or within 10 m of $h_{TC}$, the ocean was considered to be well-mixed from the surface to the thermocline and $h_S$ was reassigned to $h_{TC}$. In this case, the shallowest stable layer was the thermocline and $h_S = h_{TC}$. These thresholds and methodology were manually tested until the algorithm yielded physically consistent results across all 42 days of analysis. After these rules were applied, $h_S$, $h_B$, and $h_{TC}$ were smoothed with a running 50-min filter with 1-1-2-1-1 weighting.

The quantities $\overline{N_S^2}$ and $\overline{N_T^2}$ were determined by vertically-averaging the $N_S^2$ and $N_T^2$ fields between 0-5 m and then smoothing the resulting time series with a running 30-min filter with 1-2-1 weighting. RLs and DWLs were defined to begin when $\overline{N_S^2}$ and $\overline{N_T^2} > 1.5 \times 10^{-5} \text{ s}^{-2}$, respectively, and $h_S \leq 5$ m. Not all DWLs or RLs were associated with the creation of a new stable layer or with $h_S$ shoaling because near-surface stratification with respect to the other state.
variable (S or T) could have already existed. RL and DWL events were determined to end when $N_S^2$ and $N_T^2 < 1 \times 10^{-7}$ s$^{-2}$, respectively, or when $h_S > 5$ m, whichever event occurred first. To be classified, RL and DWL events were required to last at least 3 consecutive observations (spanning 30 total minutes) and be at least 1 h apart from stable layers of the same type.

Therefore, a RL could form in close succession to a DWL, but, in order to be classified as an individual event, the RL must be at least 1 h away from the next or previously-identified RL.

Bow $N_T^2$ profiles extended to the surface, whereas stern $N_S^2$ profiles began at 2-3 m. The bow $N_T^2$ profiles did not suggest that cold, fresh layers were deposited by rain shallower than 2 m. In other words, the $N_T^2$ data do not suggest that RLs were missing from $N_S^2$ profiles, although it is possible the T profiles did not capture all stratification events. Even if RLs began earlier or shallower than suggested by the S measurements from 2-3 m, the stable S gradients ought to mix downward past the 2-3-m measurements throughout the lifetime or decay of the RL. Therefore, our record of RLs is most likely not comprehensive, but our record should be representative of the majority of RLs that occurred at this central Indian Ocean location during DYNAMO.

Our RL and DWL identification algorithm is demonstrated on a time period beginning at 00:00 UTC, 30 min prior to sunrise (Fig. 2). On this day, which was classified as “active” MJO conditions, a DWL formed at 06:00 UTC (local noon) as $Q_{Net}$ reached $-300$ W m$^{-2}$ and $U_{10}$ decreased to below 4 m s$^{-1}$ (Fig. 2a, 2d) The DWL was marked by $h_S = 0$ m owing to the strongly positive $N_T^2$ at $z < 5$ m (Fig. 2e). Rain fell intermittently upstream of the ship during the DWL between 07:00-10:00 UTC, mid-afternoon (Fig. 2b). Rain only occurred locally at the Revelle between 09:30–10:00 UTC. Contemporaneously with the local rain accumulation, $N_S^2$ became positive over the same depths as the DWL, making this a RL-DWL combination (Fig. 2d, 2e, 2f). Stratification of both S and T disappeared at 14:00 UTC (08:00 PM) as $U_{10}$ increased
rapidly to 6-8 m s\(^{-1}\) while \(Q_{\text{Net}} \sim 100-200 \text{ W m}^{-2}\), indicating the ocean surface was cooling (Fig. 2a, 2d, 2e, 2f). Rain occurred upstream of the ship from 15:00-17:00 UTC (evening) while \(U_{10}\) reached 6-8 m s\(^{-1}\) (Fig. 2a, 2b). There was no RL observed locally as a result of this upstream rain event (Fig. 2d, 2e, 2f). Instead, \(N_S^2\) and \(N_T^2\) indicated that the ocean was well-mixed between the surface and a depth of 30 m.

Later that night at 17:00 UTC, 11:00 LST, the wind weakened (\(U_{10} < 2 \text{ m s}^{-1}\) and a large area of weak-to-moderate rain began upstream of the ship (\(R_{\text{MAX}} = 7 \text{ mm h}^{-1}\), Fig. 2a, 2b). Following this series of events, \(N_S^2\) and \(N_{S+T}^2\) became strongly positive near the ocean surface, indicating the presence of a second RL (Fig. 2d). Within this nighttime RL, \(N_T^2\) was negative due to the combined cooling effects of rain, latent, sensible, and radiative fluxes (Fig. 2e). The unstable \(N_T^2\) within the RL due to surface cooling was not large enough magnitude to render the entire layer unstable, since \(N_{S+T}^2\) (i.e. \(N^2\)) remained mostly positive (Fig. 2f). The nighttime RL lingered at \(z < 5 \text{ m}\) for over 6 hours after upstream rain ended (Fig. 2b). The daytime RL persisted 4 hours after upstream rain ended, 5 hours after local rain ended. Both RLs were coincident with 2- and 3-m depth freshening trends and fresher 2-m S compared to 3-m S (Fig. 2c), leading to stable vertical gradients of S and therefore positive \(N_S^2\) (Fig. 2d). During the DWL, RL, and RL-DWL events, \(h_S \leq 5 \text{ m}\) and the stable layer thickness, \(h_B-h_S\), was roughly 2 m (Fig. 2d, 2e, 2f). This daily analysis was used to test the stable layer identification algorithm on all 42 DYNAMO observation days.

3. Results

This section examines the frequency of occurrence of RLs, DWLs, and RL-DWLs observed throughout two MJO cycles during DYNAMO and the conditions in which these stable layers existed.
a. Stable layer occurrence and depth

From our DYNAMO record, rain and surface warming both played significant roles in creating stable near-surface ocean conditions in which \( h_S \leq 5 \) m (**Fig. 3, Table 2**). In other words, over the course of 42 observation days, 44 events occurred in which one or more stable layers was present at \( z \leq 5 \) m: 14 DWL-only events, 14 RL-only events, and 16 events in which RLs and DWLs combined one or more times. We sampled 30 DWLs (299 observation hours, 30% of the data record) and 32 RLs (165 hours, 16% of the data record). RL-DWL combinations were almost two times more likely to be RLs contained within preexisting DWLs than vice versa. For example, 10 DWLs contained one or more RLs and only 6 RLs contained DWLs; 12 RLs formed on top of preexisting DWLs but only 7 DWLs formed on top of preexisting RLs. The total number of continuous stratification events in which RLs and DWLs combined was only 16 even though 18 individual RL-DWL events were observed. This is because one DWL contained 2 RLs and another DWL formed in a preexisting RL that also later contained a new RL. RL-DWLS occupied 89 hr, or 9%, of the DYNAMO data record. RLs without DWL influence spanned only 8% of the dataset, while DWLs without RL influence spanned over twice as much (21%) of the dataset. Collectively over the course of two MJOs, daytime warming and rain caused stable layers to exist at \( z \leq 5 \) m during 38% of the dataset, and \( z \leq 10 \) m during 57% of the dataset (**Fig. 3, Fig. 4**).

When RLs and DWLs were not present, water was mixed between the surface and the thermocline, meaning the shallowest ocean stable layer was the thermocline and \( h_S = h_{TC} \) (**Fig. 3**). This situation occurred during 13% of the dataset. When RLs and DWLs decayed, these stable layers mixed downward to about 40 m depth in October 2011 (days 5-13, 21-27). In November 2011, a month during which a stable barrier layer existed between 10-30 m, RLs and
DWLs only mixed downward to about 10 m depth (Fig. 3, days 14-24). During the first November WWB pulse on 24-26 November, this barrier layer eroded and the thermocline rapidly deepened from 57 m to 90 m (Fig. 3, Fig. 4c, also discussed by Moum et al. 2014 and Chi et al. 2014). Abrupt shifts in vertical T and S stability structure were noted on 18 and 24 October and 12, 14, 15, and 18 November, which appear to be the result of advection (discussed further in Sec. 3b and by Chi et al. 2014).

RLs, DWLs, and RL-DWL combination stable layers were most frequently observed to be between 2-8 m thick, with a mean thickness of 6 m and median thickness of 4 m (Fig. 3 and Fig. 4b). These thickness observations are only slightly greater than the 2-4 m thickness estimates from previous modelling studies (Miller 1976, Price 1979, Price et al. 1986, Lombardo and Gregg 1989, and Lukas and Lindstrom 1991, Drushka et al. 2016).

While this dataset’s mean stable layer depth, $\bar{h}_S$, of 20 m agrees with the 18-m mean mixed layer depth estimate based on Argo profiles for this location in October-November from de Boyer Montegut et al. (2004) and also roughly with the 36 m mean depth from Holte et al. (2017), the high-resolution values of $h_S$ from DYNAMO were only within ±5 m of $\bar{h}_S$ during 9% of the dataset (Fig. 3, Fig. 4). In the other 91% of the dataset, the penetration depth of wind mixing was either over- or under-estimated by $\bar{h}_S$ by at least 20 m, which led to errors of 100% or greater. The standard deviation of $h_S$ was 25 m, 5 m greater than $\bar{h}_S$. Thus, $\bar{h}_S$ and the mean mixed layer depths from Argo are not representative of the daily and sub-daily upper ocean stabilization events observed during this experiment (Fig. 3, Fig. 4). For example, rain and diurnal heating stabilized the upper 5 m of the ocean on 37 out of 42 observation days, while waters were well-mixed between the surface and 40-60+ m depth on 20 out of 42 days. Instances
of $h_S = 20$ m (i.e. $h_S = \bar{h}_S$) were brief, occurring only as near-surface stable layers were forming, deepening, or decaying.

**b. Wind limits of stable layers**

The 99th percentile value of $U_{10}$ observed in the presence of stable layers was 9.8 m s$^{-1}$ for RLs, 7.6 m s$^{-1}$ for DWLs, and 5.5 m s$^{-1}$ for RL-DWLs. These values are considered to be the wind limits on each type of stable layer. Very few instances occurred in which RLs were present and $U_{10} > 10$ m s$^{-1}$ (9 data points) or in which DWLs were present and $U_{10} > 7$ m s$^{-1}$ (27 data points total, Fig. 5). The overall highest value of $U_{10}$ observed during a RL was 11.3 m s$^{-1}$, compared to 9.2 m s$^{-1}$ in a DWL and 6.3 m s$^{-1}$ in RL-DWLs (Fig. 5). Numerous previous studies have also found that DWLs are limited to times when $U_{10} \leq 7$ m s$^{-1}$ (e.g. Fairall et al. 1996b, Webster et al. 1996). Results herein are also consistent with a RL observed in the equatorial western Pacific Ocean during which $U_{10} = 9.5$ m s$^{-1}$ (Wijesekera et al. 1999). In the absence of RLs or DWLs, i.e. when the upper ocean was well-mixed, $U_{10}$ ranged from 0 to 17.6 m s$^{-1}$ and the 99th percentile value of $U_{10}$ was 13.9 m s$^{-1}$ (Fig. 5).

**c. Occurrence of stable layers throughout the MJO lifecycle**

Of the 44 continuous stable layer events observed, a similar number of events occurred in each of the suppressed, disturbed, and active periods of the MJO (13, 17, and 12 events, respectively) but only 2 stable layer events occurred in the WWB period (Table 2, Fig. 6). The occurrence of RLs and DWLs over the MJO lifecycle mirrors the well-documented evolution of $U_{10}$, $R$, and $Q_{Net}$ throughout the MJO (Table 1, Fig. 6, e.g. Zhang 2005, Rickenbach and Rutledge 1998, Johnson et al. 1999, Barnes and Houze 2013, Xu and Rutledge 2015). For example, little rain occurred during the suppressed MJO period (Fig. 6, Table 1). In these conditions, only two RL-DWL events and no RL-only events were observed (Fig. 6, Table 2).
During the disturbed and active MJO periods, $U_{10} < 8 \text{ m s}^{-1}$ and rain was frequent, intense, and long-lasting (Fig. 6, Table 1, e.g. Xu and Rutledge 2014). Within these disturbed and active MJO periods, RLs and RL-DWLs occurred once or more per day (Fig. 6, Table 2). During WWBs, when rain was frequent and long-lived but $U_{10}$ was very strong, RLs were rarely observed (Fig. 6, Table 1, Table 2). Within WWBs, mean $U_{10} = 9.1 \text{ m s}^{-1}$ and max $U_{10} = 17.6 \text{ m s}^{-1}$ (Fig. 6, Table 1). In contrast, DYNAMO observation days outside of WWBs exhibited much weaker winds, with mean $U_{10} = 3.6 \text{ m s}^{-1}$ and max $U_{10} = 11.3 \text{ m s}^{-1}$ (Fig. 6, Table 1).

Similar to results from previous studies, DWLs consistently formed on days when $Q_{\text{Net}} < -600 \text{ W m}^{-2}$ (heating the ocean), and $U_{10} \leq 7 \text{ m s}^{-1}$ (Fig. 5, Fig. 6, Fairall et al. 1996a, Webster et al. 1996, Matthews et al. 2014, Asher et al. 2015, Moulin et al. 2017). DWLs were not observed when one or both of these conditions were not met, such as on 13 October in the suppressed period, on 19, 24, and 25 October, and 22 November during disturbed and active periods, and during all WWB days (Fig. 6). As a result, DWLs of some form occurred on 92% of observed suppressed period days (all but one day), 83% of disturbed MJO days, and 70% of active MJO periods, but DWLs did not occur at all during WWBs (Table 2, Fig. 3, Fig. 6).

Of the 17 DWLs observed outside of the suppressed MJO period, 14 (82%) were actually RL-DWL combinations at one point. In other words, only three DWL-only events were observed during the disturbed and active MJO periods. RL-DWLs combinations occurred in 8/10 observed DWLs during disturbed MJO periods, and in 6/7 DWLs during active MJO periods (Fig. 6, Table 2). DWLs and RLs were only observed to overlap once at the beginning of each DYNAMO suppressed phase. No RL-DWL combinations (or DWLS) were observed during WWBs (Fig. 6, Table 2). Overall, RL-DWL combinations only occurred during 9% of the
DYNAMO period, but totaled to a substantial portion of the total 44 stable layers observed, 16 events or 36%.

d. Diurnal variability and duration of stable layers

In contrast to DWLs, RLs were observed at all hours of the day and night (Fig. 7b, 7e).

Out of 32 RLs observed, 18 (56%) existed at some point during overnight hours between sunset (00:30 UTC) and sunrise (12:30 UTC); 20 RLs (62%) existed at some point during the daytime.

During DYNAMO, rain occurred at all hours of the day but its intensity peaked in late-afternoon and also just before dawn (Fig. 7a), as is typically observed over tropical oceans (e.g. Yang and Slingo et al. 2001, Sakaeda et al. 2018). In alignment with the diurnal cycle of R, RL likelihood also peaked slightly in the afternoon, reaching 29% at 8 UTC (2 PM LST, Fig. 7b). RL likelihood was at least 7% at all other hours of the day (Fig. 7b). Both DWLs and RL-DWLs existed primarily during the daytime (2-22 UTC), with a peak in probability of occurrence between 5-10 UTC (11 AM-4 PM LST, Fig. 7e, 7h). There was a high (66-68%) likelihood of a DWL being present between 6-8 UTC (local noon to 3 PM). For RL-DWLs, the peak likelihood occurred at a similar time, from 7-9 UTC (1-4 PM LST), but the peak was not as prominent (19-23%).

Stable layers of all types were less likely to occur at night (Fig. 7b, 7e, 7h, 7k). The likelihood of continuous stable layer events, which could contain one or more RLs and/or DWLs, was as low as 10% overnight and as great as 77% at 7 UTC (1 PM, Fig. 7k). At night, $Q_{Net} > 0$, i.e. surface cooling, and hourly-mean $U_{10}$ was slightly greater than in the daytime (Fig. 7a). Both of these factors promote convection in the oceanic boundary layer, and could have contributed to the reduced occurrence of stable layers at night.
RLs formed at all hours of the day, but DWLs and RL-DWLs began preferentially during the daytime (Fig. 7e, 7f, 7i). DWLs exhibited a strong peak in hour of formation at 3 UTC, 3 h after sunrise (Fig. 7f). As a result, the peak in formation of all continuous stable layer events was also strongly peaked at 3 UTC (Fig. 7l). RLs and RL-DWLs were only slightly more likely to form at 3 and 4 UTC compared to other hours (Fig. 7c, 7i).

The average hour in which existing DWLs became absent from the upper 5 m was 14:00 UTC (1.5 h after sunset). Out of 32 total RLs observed, 11 (34%) formed at night. Four nighttime RLs lasted into the next daytime cycle and seven daytime RLs lasted at least 3 h past sunset. DWLs persisted several hours after sunset during the November suppressed period when a barrier layer existed between 10-20 m depth (Fig. 3, Fig. 7e). During these very stable upper ocean conditions, DWLs also often formed shortly after dawn.

From the Eulerian perspective of this stationary research ship experiment, RLs were observed locally over durations ≤ 14 h, RL-DWLs were observed for shorter durations (≤ 11 h), and DWLs were observed for the longest durations (≤ 21 h, Fig. 7d, 7j, 7g). The 21-h DWL event occurred on 15 Nov 2011 (Fig. 3), having formed at the surface at 2 UTC on top of a salt- and temperature-stratified barrier layer that had risen to within 5-10 m of the surface. By mid-afternoon, the base of the DWL merged with the underlying barrier layer and the combined near-surface stable layer remained within 5 m of the ocean surface until 23 UTC. Using satellite (Stuart-Menteth et al. 2002, Clayson and Bogdanoff 2013) and reanalysis (Bellenger and Duvel 2009) datasets, DWLs have been found to last over 5 days and cover expansive regions of the ocean (1000 km or more wide). From the Eulerian point of view of the ship, the mean duration of DWLs (10 h) was double the mean duration of RLs and RL-DWLs (5 h). The Lagrangian, or water-following, lifetime of stable layers could be longer than suggested by the measurements.
obtained during DYNAMO. The average duration of all continuous stable layer events was 8 h (Fig. 7m). Minimum RL, DWL, and RL-DWL durations were all 30 minutes because of the 10-minute resolution of this dataset. Given the average speed of the surface current during each RL, the equivalent mean and maximum length scales of RLs were 9.2 and 33.2 km. However this length-scale estimate is approximate because it does not account for lateral mixing of the RL or the spatial and temporal heterogeneity of precipitating systems (Wijesekera et al. 1999, Soloviev and Lukas 2006, Houze et al. 2015).

The longest-lasting RL was one that formed in a DWL (14 h). The mean durations of RLs with and without DWL influence were not significantly different. Similarly, DWLs with and without RL influence were not necessarily longer or shorter; both DWL varieties had a mean duration of 10 h. Ignoring the relative timing of T and S stratification, the overall mean duration of RL-DWL combinations was 5 h (Fig. 7j). RLs that formed on DWLs and DWLs that formed on RLs could be phenomenologically distinct, but a larger dataset of these features is required to precisely determine their differences. Thus, these two cases have been combined into a single category, RL-DWLs, for this study.

4. Stable Layer Estimates

This section seeks a better understanding of the observed depth (Fig. 3, Fig. 6) and wind limits (Fig. 5) of stable layers by examining estimates of each quantity:

(1) the upper ocean stable layer depth, $\hat{h}_S$; and

(2) the highest values of $U_{10}$ at which stable layers persist and form, $\tilde{U}_S$.

a. Stable layer depth: $\hat{h}_S$

To clarify the relationship between $h_S$ and $U_{10}$, we consider $B$, the surface buoyancy flux into the ocean produced by the combined effects of rain and heating (Fig. 8, Appendix A, Fig.
A1, *Dorrestein 1979*), and \( u_{W*}^3 \), the cubed friction velocity in the water, which we consider to represent the rate of turbulent kinetic energy (TKE) input to the ocean surface by the wind; \( u_{W*}^3 \) \([\text{m}^3\text{s}^{-3}]\) is opposed by \( B \) \([\text{m}^2\text{s}^{-3}]\). The value of \( B \) is a function of surface water properties, \( Q_{\text{Net}} \), and \( R \). For reference from Appendix A:

1. \( R = 10 \text{ mm h}^{-1} \), a typical tropical oceanic rain rate (*Thompson et al. 2015*), produces the same buoyancy as \( Q_{\text{Net}} = -850 \text{ W m}^{-2} \), the median daily max value of surface heating during DYNAMO. According to this dataset, max \( R = 188 \text{ mm h}^{-1} \) and 30\% of \( R \) observations exceeded 10 mm h\(^{-1}\), which was also shown by *Thompson et al. (2015)* for two long-term IndoPacific warm pool datasets of \( R \). During DYNAMO, \( Q_{\text{Net}} < -850 \text{ W m}^{-2} \) during only 1\% of observations (min \( Q_{\text{Net}} = -1035 \text{ W m}^{-2} \)). Therefore, rain can produce \( B \) that is more than an order of magnitude greater than is typically produced by surface heating (Fig. 8).

2. The buoyancy produced by \( R = 5 \text{ mm h}^{-1} \) is equal and opposite to the buoyancy destroyed by a surface cooling on the order of \( Q_{\text{Net}} = 400 \text{ W m}^{-2} \), which is the maximum nighttime \( Q_{\text{Net}} \) outside of WWB periods and maximum observed latent heat flux, \( Q_{\text{Lat}} \). Since \( R = 5 \text{ mm h}^{-1} \) is a relatively weak rain rate and \( Q_{\text{Net}} = 400 \text{ W m}^{-2} \) is a very high cooling rate, buoyancy produced by rain typically stabilizes negative buoyancy produced by surface cooling.

3. Buoyancy produced by rain freshening is 15 times greater than negative buoyancy produced by rain cooling, meaning the cooling effect of rain on \( B \) can be ignored. \( B \) produced by rain is always positive, which can lead to stratification of the upper ocean.

From a 1-D perspective and neglecting shear- and wave-driven turbulence, Monin-Obukhov scaling suggests that \( B \) will be mixed by wind stress to an estimated depth of \( \hat{h}_S \) given by:

\[
\hat{h}_S = \frac{u_{W*}^3}{kB}
\]
where $\kappa = 0.40$, the von Kármán constant, or

$$\hat{h}_S = C \frac{U_{10}^3}{B} \quad [8]$$

where the constant $C$ includes the densities of seawater and air, $\rho_w$ and $\rho_{air}$, and a drag coefficient, $C_D \sim 0.8$-1x10^{-3} (Edson et al. 2013):

$$C = \frac{1}{\kappa} \left(\frac{C_D \rho_{air}}{\rho_w}\right)^{3/2} \approx 5.42 \times 10^{-9} \quad [9]$$

[8] and [9] arise from the fact that the flux of momentum is continuous across the sea surface such that $\tau = \rho_w u_w^* = \rho_{air} u_{air}^*$, where the $\tau$ in the air is approximated by $C_D \rho_{air} U_{10}^2$.

According to observations, if surface water is less dense than underlying water, $h_S \sim 0$ m and $h_S$ marks the top of a stable layer that is in contact with the surface (Fig. 2, Fig. 3). In [7] and [8], $\hat{h}_S \sim 0$ for very large $B$ and weak values of $u_w^*$ or $U_{10}$, respectively. Equations [7] and [8] result from the assumption that the stable layer depth, $h_S$, responds to changing production and consumption of TKE. This approach is in contrast to a Richardson number constraint, which is applied with mixed layer models or simple layer-averaged slab models (Fairall et al. 1996a).

By isolating DYNAMO data for periods when $B > 0$, close agreement was found between $\hat{h}_S$ and $\hat{h}_S$ (Fig. 9, in which $h_S$ was temporally-averaged by a 1-h moving mean filter and $\hat{h}_S$ was temporally-averaged by a 2-h moving mean filter). Of 44 total observed stable layers, 36 were successfully predicted to exist at $z \leq 5$ m by $\hat{h}_S$ within the same time span that they occurred according to $h_S$ (Fig. 9). This equates to an 88% success rate in terms of stable layer prediction.

All DWLs, all RL-DWLs, and all but 8 short-lived RLs were predicted by $\hat{h}_S$. During times when $\hat{h}_S$ mirrored $h_S$, we assume that the buoyancy and wind mixing forces described in [7, 8] were the dominant factors controlling the depth of upper ocean stratification, $h_S$. When $B < 0$, the ocean should mix vertically due to convective overturning by surface cooling or extreme
salinification. However, when $B < 0$, $\hat{h}_S$ also becomes negative, the latter of which is non-physical and is therefore not shown in Fig. 9. The estimated stable layer depth $\hat{h}_S$ was able to account for observed near-surface stratification better than the observed mean value, $\overline{h}_S = 20$ m, or the monthly mean mixed layer depths, $h_{M1}$ and $h_{M2}$, determined by two previous studies for this location in October and November (Fig. 9, de Boyer Montégut et al. 2004: 17 and 19 m; Holte et al. 2017: 34 and 37 m, respectively). The oscillation of $h_S$ between its two extrema, near-surface stratification or deep mixing, was not random, i.e. $h_S$ did not randomly vary about $\overline{h}_S$. Rather, the $h_S$ oscillations systematically coincided with the occurrence of either buoyancy production by rain and solar heating or buoyancy destruction by wind (Fig. 6, Fig. 8, Fig. 9).

Several 1-2 h temporal differences existed between estimated $\hat{h}_S$ and observed $h_S$ (Fig. 9).

These temporal differences appear reasonable given that $h_S$ is an observation of a present state, whereas $\hat{h}_S$ is a prediction of a future equilibrated state given the present values of $B$ and $U_{10}$.

Moreover, temporal and spatial averaging were performed in the estimation of both $\hat{h}_S$ and $h_S$ time series, and S measurements were not collected at $z < 2$-3 m. For instance, the 1-2 h temporal differences between $\hat{h}_S$ and $h_S$ appear understandable because RLs initially form within the top several centimeters of the ocean (Drushka et al. 2016), they often propagate laterally (Soloviev et al. 2015), and a finite amount of time is required for freshwater to be mixed and diffused downward past the 2-3 m salinity measurements used in this study (Asher et al. 2014).

All of these aforementioned issues and processes could have contributed to the frequently-observed 1-2 h timing offset between $h_S$ and $\hat{h}_S$.

Aside from these slight timing differences, three additional differences were evident between $\hat{h}_S$ and $h_S$ (Fig. 9):
False Negatives: eight RLs were observed but not predicted, all of which occurred after
sunset on 10/17, 10/19, 10/22 (the second RL in Fig. 2), 10/27, 11/18, 11/19 11/20, and
11/22. These RLs were 1.5-4 h in duration. Local rain occurred during only two of the
missed RLs, whereas upstream rain was observed within 3 h of all eight events. These RLs
may have resulted from advection of near-surface freshwater. This could have led to their
under-prediction by \( \hat{h}_S \), which relies on current conditions to predict stable layer existence.
One of the missed RLs formed inside a DWL that was correctly predicted, and that was
already in contact with the barrier layer (11/19).

False Positives: three RLs were predicted but not observed. These occurred during WWBs
when contemporaneous Revelle measurements showed that sub-surface turbulence was
higher than would be expected from wind alone, having been enhanced by shear across a 50-
100 m depth Wyrtki Jet (Moum et al. 2014).

Under-Predicted Duration: several DWLs, RLs, and RL-DWLs were observed to last longer
than predicted. DWLs and RLs can harbor stability near the surface well after \( B \) ceases to be
positive, particularly if \( U_{10} \) is weak, according to model simulations by Drushka et al. (2016).
For instance, several DWLs lasted 3 h after sunset and the maximum observed duration of
DWLs and RLs was 21 and 14 h, respectively (Fig. 7), i.e. longer than the length of daytime
(12 h in this study) or the duration of individual rain events. Some of the stable layers with
underestimated duration occurred when the surface stable layers merged with the underlying
barrier layer (Fig. 4), meaning that the barrier layer could have influenced the lifecycle of
certain stable layers. Under-predicted stable layer duration could also result from under-
estimates of surface freshwater advection. The value of \( B \) was calculated with \( R_{\text{MAX}} \), the
maximum \( R \) observed from either the ship’s gauges or the ship’s radar within a sector.
spanning 9 km in the upstream direction (roughly a 3-h advective time scale) and 4 km in all other directions (Sec. 2, Fig. 1). We acknowledge the limitation of this method to account for the spatial heterogeneity of $B$ due to rain.

b. Stable layer wind limit: $\bar{U}_S$

[8] and [9] can be rearranged to describe the wind limit of stable layers, $\bar{U}_S$, defined as the highest value of $U_{10}$ in which stratification should exist at the depth $h_S$ for a given value of $B$:

$$\bar{U}_S = \left( \frac{\hat{h}_SB}{C} \right)^{1/3} \approx 569(\hat{h}_SB)^{1/3} \tag{10}$$

If $B > 0$ and $U_{10} \leq \bar{U}_S$, then conditions should be favorable for the formation and persistence of stable layers at depths of $z \leq h_S$. On the other hand, if $B > 0$ but $U_{10} > \bar{U}_S$, surface-forced mixing should outweigh buoyancy suppression and neither DWLs nor RLs should form at $z \leq h_S$. In other words, wind mixing will homogenize $T$ and $S$ in a layer extending from the surface downward to the barrier layer or the thermocline (Fig. 3, Fig. 9).

Solutions for [7, 8, 10], appear in Fig. 10 for $h_S = 1, 2$, and 5 m: $u_{w^*}^3$ and $B$ are related linearly (Fig. 10a), whereas $\bar{U}_S$ is proportional to $B^{1/3}$ (Fig. 10b). In these figures, lines of constant $h_S$ show that stable layers should form at these depths for a given $B$ and $u_{w^*}^3$ (Fig. 10a) and therefore $U_{10}$ (Fig. 10b). Alternatively, the lines of constant $h_S$ also indicate the highest values of wind mixing that can take place while stable layers either form or persist for a given $B$.

From [10], the stable layer wind limit, $\bar{U}_S$, is equal to 8.6 m s$^{-1}$ for $R = 50$ mm h$^{-1}$ and $h_S = 1$ m, which means that $R = 50$ mm h$^{-1}$ should maintain a RL with stable $dS/dz$ gradients as shallow as 1-m depth so long as $U_{10} \leq 8.6$ m s$^{-1}$. For the same $R$ value and $h_S = 5$ m, the wind limit of RLs increases to $\bar{U}_S = 13.6$ m s$^{-1}$, which is only slightly higher than the greatest value of $U_{10}$ observed in a RL: 11.3 m s$^{-1}$ (Fig. 5). Values of $\bar{U}_S$ range between 8.0-13.6 m s$^{-1}$ for $R$ between 10-50 mm h$^{-1}$, while $\bar{U}_S = 8.4$ m s$^{-1}$ for the maximum observed surface heating: $Q_{\text{Net}} = -1035$ W m$^{-2}$ [10].
This estimated wind limit on DWLs is close to the observed wind limit, $U_{10} = 7.6 \text{ m s}^{-1}$ (the 99th percentile value of $U_{10}$ when DWLs were present, Fig. 5). An additional interpretation of these calculations is that a DWL may persist at $z \leq 5 \text{ m}$ when $U_{10} = 8.4 \text{ m s}^{-1}$ if $Q_{\text{Net}}$ is maximized ($-1035 \text{ W m}^{-2}$), while a RL may persist at the same depth and during the same wind speed even if $R$ is only moderate (12 mm h$^{-1}$). Since instances of $R > 12 \text{ mm h}^{-1}$ are frequent, [8] and [10] can explain observations of RLs persisting at higher $U_{10}$ than DWLs (Fig. 5, Fig. 10).

For all instances in which stable layers were present, 46% of DWL-only, 70% of RL-only, 70% of RL-DWL, and 66% of all stable layer instances occurred when $U_{10} < \bar{U}_S$ and $B > 0 \text{ m}^2 \text{s}^{-3}$, when $\bar{U}_S$ was evaluated with [10] assuming $h_S = 5 \text{ m}$. These percentages represent the success rates at which near-surface stable layer occurrence can be estimated by determining times when $U_{10} < \bar{U}_S$ and $B > 0 \text{ m}^2 \text{s}^{-3}$.

The $\bar{h}_S$ and $\bar{U}_S$ methods predicted 36 out of 44 total stable layers to occur within the same time span that they were observed, leading to an overall success rate of 88% (Fig. 9). The remaining eight missed stable layers were RLs of relatively short duration, between 1.5-4 h, that occurred within 6 h of other observed (and successfully predicted) stable layers (Fig. 9). In other words, all observed DWLs, all observed RL-DWLs, and 75% of observed RLs were successfully predicted to occur within observed stable layer time spans.

The occurrence of $U_{10} < \bar{U}_S$ and $B > 0 \text{ m}^2 \text{s}^{-3}$ was much more likely prior to the WWB (Fig. 5, Fig. 8, Fig. 9). Values of $U_{10}$ were rarely low enough to support stable layers during WWBs, despite high $B$ during this period (Fig. 8, Fig. 9). For example, only three RLs and no DWLs were observed in WWBs. In suppressed, disturbed, and active MJO periods, conditions in which $U_{10} < \bar{U}_S$ and $B > 0 \text{ m}^2 \text{s}^{-3}$ occurred at least once per day (Fig. 5, Fig. 9). Stable layers were frequently observed and predicted to occur during these periods (Fig. 9).
Both $U_{10}$ and $R$ were necessary for determining the likelihood of RL formation (Fig. 11), while $Q_{\text{Net}}$ alone could serve as a useful predictor for DWL occurrence (Fig. 5, Fig. 11). For example, DWLs were only present during 15% of the time when $Q_{\text{Net}} > 0$ W m$^{-2}$, and never formed in these conditions, whereas DWLs were present 99% of the time when $Q_{\text{Net}} < -600$ W m$^{-2}$ (Fig. 11a). The value of $Q_{\text{Net}} < -500$ W m$^{-2}$ during every observed DWL (Fig. 11a, Fig. 6).

Thus, to a certain extent, the magnitude of $Q_{\text{Net}}$ was a useful predictor of DWL occurrence even without consideration of $U_{10}$ (Fig. 11b). In contrast, many instances of $R = 0$ mm h$^{-1}$ occurred leading up to RL formation and when a RL was present. The probability distribution functions of $R$ were also not statistically different between times with or without the presence of a RL (Fig. 11b). In other words, RLs were not statistically more likely to occur at any $R$ range except when $R > 100$ mm h$^{-1}$, and these high rain rates represent a small fraction of the total $R$ distribution.

Therefore, the $h_S$- and $\bar{U}_S$-based estimate of stable layer occurrence, which incorporates both $U_{10}$ and $B$ (i.e., $R$), was more successful in determining the likelihood of RL formation compared to predicting the existence of a RL using $R$ alone (Fig. 11d).

5. Discussion

The presence of near-surface stable layers is important for coupled climate processes because they limit the vertical extent of wind-driven ocean mixing and the distribution of atmospheric forcing into the ocean (e.g., Price et al. 1986, Fairall 1996a). When either DWLs, RLs, or their combinations are present, turbulent mixing must first supply enough kinetic energy to homogenize the near-surface stable layers before mixing can extend deeper into the ocean column. While formation of a DWL is limited to daytime since it requires solar warming, a RL can form at any time. Furthermore, a RL may form within an existing DWL, and a DWL may
form within an existing RL (Fig. 2, Fig. 6). These two cases are considered together as RL-DWL combinations in this study, though they could be phenomenologically distinct.

Based on the stable layer observations and estimates presented in Sec. 3 and Sec. 4, we hypothesize that the top depth of RLs and DWLs, $h_S$, can be reasonably predicted as $\hat{h}_S$ in terms of $U_{10}$ and $B$ and that the upper limit of $U_{10}$ at which RLs and DWLs can form and persist, $U_S$, can be estimated in terms of $B$. This suggests that reasonable estimates of $\hat{h}_S$ might be produced from datasets of $U_{10}$ and $B$ over tropical oceans in which neither advection nor current shear are dominant forces in the budgets of ocean buoyancy or momentum (Fig. 9). Measurements of $U_{10}$ and $B$ are collected by moorings, ships, autonomous vehicles, and satellites. Estimates of $U_{10}$ and $B$ are also available from several global products based on observations, such as reanalysis, TropFlux (Praveen Kumar et al., 2012), and SeaFlux (Curry et al., 2004). Therefore, without the use of subsurface ocean measurements, the $\hat{h}_S$ and $\hat{U}_S$ estimates could help determine when and where the vertical extent of ocean mixing is limited to shallow depths of $z \leq 5$ m.

Furthermore, we hypothesize that the occurrence of RLs and DWLs throughout the MJO is regulated by intraseasonal variations in $U_{10}$, $Q_{Net}$, and $R$ as well as the local balance between $B$ and $U_{10}$ (Table 2, Fig. 6, Fig. 9). Throughout the two MJO cycles observed during DYNAMO, RLs withstood $U_{10} \leq 9.8$ m s$^{-1}$, while DWLs only survived $U_{10} \leq 7.6$ m s$^{-1}$ (99th percentile values). RLs were also much less likely to occur when $R_{MAX}$ decreased below 5 mm h$^{-1}$ (Fig. 8), which can explain the rare occurrence of RLs during suppressed MJO periods when $U_{10} < 8$ m s$^{-1}$ but when sky conditions were mostly clear with little rain (Fig. 6). RLs and RL-DWLs were most likely to occur during disturbed and active MJO periods, which exhibit frequent, heavy rain and $U_{10} < 8-9$ m s$^{-1}$ (Table 1) During WWBs, $U_{10}$ was between 7-10 m s$^{-1}$, leading to only 2 observed RLs despite persistently high $B$ from rainfall during this period (Fig. 6, Fig. 8, Fig. 9).
WWB conditions, characterized by both net surface cooling and high $U_{10}$, were even less suitable for DWL formation: no DWLs were observed during WWB periods. Near-surface stratification during WWB periods was also diminished by shear-driven turbulence generated from a Wyrtki Jet in the upper 50-100 m (Moum et al. 2014). DWLs without RL influence were most common in suppressed periods when strong net ocean heating occurred in conjunction with little rain and light wind conditions ($U_{10} < 7$ m s$^{-1}$) during 95% of suppressed periods, Fig. 6. DWLs also occurred in disturbed and active periods, but 83% of these occurred in combination with RLs at some point (Table 2, Fig. 6, Fig. 9).

Compared to DWLs alone, RLs and RL-DWLs occurred closer in time to the beginning of the active MJO period, when the most intense atmospheric convection tends to occur, and also occurred closer in time to WWB periods, when rain was more often stratiform (longer duration and lighter intensity) and $U_{10}$ was stronger (Fig. 6, atmospheric conditions as a function of MJO phase discussed further in Benedict and Randall 2007, Xu and Rutledge 2014).

Rain’s impact on near-surface ocean stability and mixing throughout the MJO should not be ignored. Throughout the two MJOs, RLs created conditions during which turbulence was limited to the upper few meters of the ocean rather than the seasonal mean mixed layer depth described by CTD and Argo climatologies (Fig. 9). RLs were observed to form at least as often
as DWLs (32 vs. 30 events), several RLs were observed to persist locally for 10-14 h, and RLs were observed at all times of the day and night (Table 2, Fig. 6, Fig. 7). Since RLs played a significant role in establishing near-surface ocean stratification (occupying 16% of the dataset), analysis of upper ocean stability based on temperature or DWLs alone is incomplete outside of suppressed MJO periods.

Global investigations of RL coverage have not yet been completed. Similar to this study’s findings, RLs at other latitudes are also likely to cover smaller areas and shorter time period than DWLs due to the localized area and short duration of rain events compared to the coverage of cloud-free, low-wind conditions required to form DWLs. Large areas of tropical, subtropical, and midlatitude oceans may be cloud-free at any given time. In contrast, rainfall is narrowly concentrated across equatorial latitude bands due to the Intertropical Convergence Zone, monsoons, and the MJO, as well as broadly distributed across the midlatitudes associated with the passage of large low pressure systems (e.g. Pendergrass and Deser 2017). If the sensitivity of RL formation and persistence to $U_{10}$ is also considered, the global coverage and frequency of RLs would be even lower than suggested by rain climatologies alone. This hypothesis was confirmed by simulations conducted by Drushka et al. (2016) for tropical regions using a 1-D turbulence-allowing ocean model and reanalysis data.

Results presented herein should motivate future studies regarding coupled numerical models and observational analysis. The tendency for DWLs and RLs to coexist (16 continuous events) and for overnight RLs to last into the next daytime cycle (4 events) suggests that parameterizations for near-surface stratification should be designed so that RLs and DWLs can form in the same place and evolve concurrently. The results indicate that RL formation and persistence were strongly related to instantaneous rain rate, $R$, on 10-min time scales. Therefore,
the accuracy of predicted or assimilated rain on these timescales will impact the fidelity of simulated upper ocean stratification in numerical models. Model mixing schemes will also determine the simulated impacts of rain and surface warming on the ocean. Since RLs, DWLs, and their combinations were typically between 2-4 m thick vertically with \( h_S \leq 5 \) m (Fig. 4), 1-m vertical resolution in the upper 5-10 m appears critical for observational and modeling experiments regarding RLs and DWLs. Argo floats, bathythermograph measurements, and most moorings have historically observed S and T at 1-5 m depth with 2 m vertical resolution, which have not consistently captured near-surface RLs or DWLs (Gould et al. 2004, Anderson and Riser 2014). The frequent occurrence of RLs and DWLs in tropical oceans would also be completely ignored in coupled model results that rely on mean or slab mixed layer depths. A review of MJO air-sea coupled processes by DeMott et al. (2015) does not recommend configuring coupled models with mean or slab-ocean mixed layer depths. For instance, the DYNAMO stable layer depth, \( h_S \), was only within ±5 m of the 20-m mean value of \( h_S \) for 9% of this dataset. The dominant modes of variability in the upper Indian Ocean observed throughout MJOs during DYNAMO can be more accurately summarized in two ways (Fig. 9): (1) rain and/or diurnal heating stabilized the upper 5 m of the ocean and limited wind mixing to these shallow depths on 37/42 days, 38% of the time; (2) turbulence and ocean convection mixed the water from the surface to at least 40 m depth on 20/42 days, 62% of the time.

6. Conclusions

Near-surface ocean stable layers limit the penetration depth of wind mixing and the vertical distribution of atmospheric fluxes of momentum, freshwater, and heat. Therefore, the presence of near-surface ocean stable layers can amplify both sea surface temperature and sea surface salinity variability (SST and SSS). Leading up to this study, diurnal warm layers (DWLs)
resulting from surface heating were more comprehensively understood compared to rain layers (RLs) resulting from precipitation; both RLs and DWLs are statically-stable near-surface layers. While DWLs were known to frequent the low-wind, high-insolation suppressed period of the Madden-Julian Oscillation (MJO), the frequency at which RLs or their combinations with DWLs occurred throughout the MJO was unknown. The current study used central Indian Ocean ship-based observations of rain, wind, and vertical gradients of ocean temperature and salinity to better understand the following features of RLs, DWLs, and RL-DWLs: their formation and persistence as a function of $U_{10}$ and B, as well as their occurrence as a function of MJO phase. Tracking of 30 DWLs, 32 RLs, and 17 RL-DWL combinations from a stationary research vessel revealed that, throughout two MJO events:

- RLs and DWLs stabilized the ocean at depths of $z \leq 5$ m in 38% of the dataset.
- Although RLs were more numerous than DWLs, 32 vs. 30 events, RL duration was usually shorter. RLs and RL-DWLs were observed with durations $\leq 14$ and $\leq 11$ h (mean duration = 5 h), whereas DWLs were observed with longer durations $\leq 21$ h (mean duration = 10 h).
- During 16% of the dataset, RLs of some kind occurred; in 30% of the dataset, some form of DWLs occurred.
- RLs and RL-DWL combinations primarily formed in disturbed and active MJO conditions, usually forming at least once per 24 hours in these periods.
- DWLs without RL influence usually occurred daily in suppressed MJO conditions and occurred rarely thereafter.
- Of the 17 DWLs that occurred in the disturbed and active MJO periods, all but three combined with an RL at some point.
During westerly wind burst (WWB) conditions, DWLs were not detected and RLs formed rarely.

When DWLs were present, 99% of $U_{10}$ values were below 7.6 m s$^{-1}$. When RLs were present, 99% of $U_{10}$ values were below 9.8 m s$^{-1}$.

RLs contained enough buoyancy to withstand nocturnal ocean convection and surface cooling. RLs forming during the day were often observed to persist through the day-to-night transition. RLs forming at night were often observed to persist through the night-to-day transition.

An estimate for stable layer depth, $\hat{h}_S$, was developed based on $U_{10}$ and the buoyancy flux, $B$. This led to an estimate for $\hat{U}_S$, the maximum $U_{10}$ at which stable layers should exist at depth $h_S$ for fixed B. These stable layer estimation methods predicted 88% of the observed stable layer events (36 out of 44 events) during the time span in which they were observed.

The different occurrence rate of RLs vs. DWLs throughout the MJO cycle appears to be explained by variations in $Q_{\text{Net}}$, $R$, and $U_{10}$ throughout the MJO, and by the fact that RLs can withstand higher $U_{10}$ than DWLs. For instance, RLs and RL-DWL combinations tended to occur in disturbed and active MJO periods, whereas DWLs alone were more frequent in suppressed MJO periods.

The 20-m mean value of stable layer depth, $\overline{h}_S$, was almost never observed. Use of $\overline{h}_S$ in place of observed $h_S$ would have led to an over- or under-estimation of the penetration depth of wind mixing in 91% of the dataset, in which case errors exceeded 100%. Similar errors would have been caused by monthly mean mixed layer depths derived from climatologies of Argo profiles, which were similar to this study’s estimate of $\overline{h}_S$.

The distribution of observed stable layer depth, $h_S$, was bi-modal, centered at 0-5 m during
near-surface stable layers or centered at 40-70 m when water was well-mixed from the surface
to the thermocline.

Appendix A: Surface Buoyancy Flux into the Ocean

From Dorrestein (1979), the surface buoyancy flux into the ocean is

\[ B = \frac{g}{\rho_w} \left[ S_0 \beta (P - E) - \frac{\alpha}{c_p} (Q_{Lat} + Q_{sens} + Q_{Solar} + Q_{IR}) + \alpha \Delta TP \right] \]  \[11\]

<th>Term</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Rain Freshening</td>
<td>Heating</td>
</tr>
<tr>
<td>and Evaporation Term</td>
<td>Rain Cooling</td>
</tr>
</tbody>
</table>

Table A1 explains the variables, constants, and typical values for components of \( B \) in [A1]. The first term of [A1] conveys how the precipitation mass flux, \( P \), makes the surface layer more buoyant, i.e. less dense, whereas evaporation mass flux, \( E \), increases surface salt content and therefore increases surface seawater density. The second term of [A1] describes the generation of buoyancy by surface heating (stabilization) and the destruction of buoyancy by surface cooling (destabilization). Similar to the heating term of [A1], the rain cooling term of [A1] accounts for surface heat loss and layer destabilization by the rain-sea temperature difference (Gosnell et al. 1995, Fairall et al. 1996b).

To evaluate [A1], the rain rate, \( R \), must be multiplied by the density of pure water, \( \rho_{PW} = 1000 \text{ kg m}^{-3} \), to determine the precipitation mass flux, \( P \), in kg m\(^{-1}\) s\(^{-1}\):

\[ P = \rho_{PW} R \]  \[12\]

Similarly, the evaporation mass flux, \( E \) in kg m\(^{-1}\) s\(^{-1}\), is determined by:

\[ E = Q_{Lat} \rho_{PW} L_v \]  \[13\]

where \( L_v \) is the latent heat of vaporization, 2.25\times10^6 to 2.5\times10^6 at 100°C to 0°C, respectively.

When evaluated with central Indian Ocean observations of fluxes, \( R \), and surface water properties, \( B \) is widely distributed between \( -3\times10^{-7} \) and \( 2\times10^{-5} \) (Fig. A1). The most frequent values of \( B \) are negative, corresponding to persistent evaporation and cooling by the sensible, latent, and radiative heat fluxes (minimum \( Q_{Net} = 400 \text{ W m}^{-2} \)). The maximum rate of evaporation
that was observed during DYNAMO was 0.6 mm h\(^{-1}\), over two orders of magnitude lower than the maximum rain rate that was observed: 184 mm h\(^{-1}\) measured within 8 km upstream of the ship radar and 96 mm h\(^{-1}\) measured by the ship rain gauge. Compared to the net heat flux, rain produced values of \(B\) that were distributed over a wider range and were of much greater magnitude (Fig. A1). [A1] shows that equivalent \(B\) is produced by a median daily max heating rate of \(Q_{\text{Net}} = -850\) W m\(^{-2}\) and relatively weak rain rate of \(R = 10\) mm h\(^{-1}\). Maximum \(Q_{\text{Net}}\) observed during DYNAMO was \(-1035\) W m\(^{-2}\), which produced only slightly larger \(B\) (Fig. A1).

\(B\) due to interfacial turbulent/radiative heat exchanges, \(B_Q\), can be systematically separated from \(B\) contributed by rain, \(B_R\):

\[
B = B_Q + B_R \tag{14}
\]

\[
B_R = \frac{g}{\rho_W} P(S_0\beta + \alpha \Delta T) \tag{15}
\]

\[
B_Q = \frac{g\alpha}{\rho_W c_p} \left[ \left( 1 - \frac{\beta c_p}{\alpha L_V} S_0 \right) Q_{\text{Lat}} + Q_{\text{Sens}} + Q_{\text{Solar}} + Q_{\text{IR}} \right] \tag{16}
\]

\(B_Q\) and \(B_R\) are compared in Fig 8. The value of \(B_R\) is often over an order of magnitude greater than the value of \(B_Q\), yet instances of positive \(B_R\) are more episodic compared to the sinusoidal manner of positive \(B_Q\).

Evaluation of [A5] with central Indian observations from Table A1 implies that the stabilizing rain-freshening term, \(S_0\beta\), is about 15 times the destabilizing rain-cooling term, \(\alpha \Delta T\), in [A5]. This means that the stabilizing effect of rain freshening on surface buoyancy is 15 times larger than the destabilizing effect of rain cooling on surface buoyancy. Therefore, the effect of rain cooling on \(B\) and \(B_R\) can be ignored. \(B_R\) is always a positive, stabilizing flux, as shown in Fig. 8 for the entire DYNAMO experiment.
The factor $\frac{\beta c_p}{\alpha L_V} S_0$ in [A6] is about 0.10 in the tropics using values from Table A1, so in regard to $B$ and $B_Q$, the effect of evaporative cooling is overwhelmingly larger than the effect of evaporative salinification, which is also shown in Table A1 and by Asher et al. (2015).

Despite the fact that this study finds rain freshening to be responsible for greater $B$ than solar heating (Fig. 8), [A1] and [A6] actually overestimate the stabilizing effect of the net solar flux ($Q_{Solar}$) because, unlike the net longwave flux ($Q_{IR}$) that is absorbed within the top 10 μm, $Q_{Solar}$ is not entirely absorbed at the interface. Instead, roughly 50% of $Q_{Solar}$ is absorbed within the top 0.5 m and the remainder is absorbed over the top 5-9 m (see Table 3 in Fairall et al., 1996a).

Appendix B: Processing of Precipitation Radar Data

The standard Yuter and Houze (1998) convective and stratiform radar echo partitioning algorithm was applied to the $Z_h$ field at the lowest vertical level, which was at 0.75 km above sea level. The algorithm’s tunable parameters were tested to produce the most physically-realistic partitioning between convective and stratiform portions of storms in this dataset (Steiner et al. 1995, Yuter and Houze 1998, Houze 1997, Schumacher et al. 2003, Thompson et al. 2015).

Vertical cross sections of radar data were investigated during algorithm testing to ensure that stratiform rain classification was only made where a clear, robust radar bright band was occurring. Therefore, stratiform rain designations were only made when vertical profiles of radar data indicated that a melting layer and stratiform rain microphysical processes were both occurring. As part of the algorithm’s standard procedures, background $Z_h$ was smoothed about a 4 km radius of each grid point. The algorithm’s climatological parameters were $a = 60$ and $b = 100$. First, grid points were classified as convective when $Z_h$ exceed the smoothed background $Z_h$.

by 17 dBZ. Following standard procedures, neighboring grid points within 2, 3, 4, 5, and 6 km range from these convective grid points were also classified as convective if $Z_h$ exceeded the following thresholds, respectively: 25 dBZ, 25-30 dBZ, 30-35 dBZ, 35-40 dBZ, and 40 dBZ.

In order to calculate $R$ at each radar grid point, $Z_h$ [dBZ] was first converted into linear units, $z$ [mm$^6$ m$^{-3}$] via: $z = 10^{(0.1 Zh)}$. Then $R$ was calculated at each grid point using two power law estimators, one for convective points: $R = 0.0366 z^{0.684}$, and another for stratiform points: $R = 0.0258 z^{0.644}$. These $R$ estimators were developed by Thompson et al. (2015) for tropical oceanic rainfall experienced over the Indo-Pacific Warm Pool. If radar echo partitioning into convective and stratiform areas can be performed with confidence, using separate $R$ estimators for convective and stratiform rain can significantly reduce error associated with $R$ estimation (Thompson et al. 2015).

Table 1: Meteorological conditions during two MJOs observed during this DYNAMO dataset.

MJO conditions at R/V Revelle location (80.5°E, 0°) according to Wheeler and Hendon (2004) RMM Index ([http://www.bom.gov.au/climate/mjo/graphics/rmm.74toRealtime.txt](http://www.bom.gov.au/climate/mjo/graphics/rmm.74toRealtime.txt)). Time periods defined in this study start or end at 00Z except when denoted by superscript # = 08Z; @ = 10Z; $ = 17Z; % = 22Z. Two WWB pulses occurred during the November active MJO phase. Mean rain rate and wind speed calculated from Revelle gauge measurements. Sign convention for net heat flux is negative into the ocean (heating the ocean). The mean daytime minimum value and mean daytime value of net heat flux, $Q_{Net}$, were tracked. Daytime hours were considered to be 7 AM – 5 PM LST, 1-11 UTC. *The DYNAMO time periods in which complete vertical profiles of the ocean were measured at Revelle did not span all phases of the RMM index. Observation days did not include phases 4, 5, or 6. Observations were also not collected on all days of phases 7 or 3 (see Sec. 2a for details).

Table 2: Stable layers observed throughout two MJO lifecycles.

Count of observed stable layers in each MJO period defined by the RMM Index (Table 1, Sec. 2a). The continuous stable layer event category counts events in which multiple RLs and/or DWLs were present at the same time as a single continuous event. Events in which RLs and DWLs combined occurred 18 individual times but contributed to only 16 continuous stable layer events because 2 RL-DWL events were contained within preexisting stable events in which another RL-DWL was also present. The total number of continuous stable layers is equal to the sum of stable layers in RL-only, DWL-Only, and RL-DWL categories.

Figure 1: R/V Revelle (0°, 80.5°E, position denoted by center circle) radar reflectivity ($Z_h$) with outline of rain sector area (thick black line). The sector extends 9 km from Revelle in the upstream direction and within 4 km of Revelle in all other directions. The upstream extension of the sector accounts for surface advection of rainwater within approximately the last 3 h by the mean 0.8 m s$^{-1}$ eastward current during these cruises.
Figure 2: 22 October 2011 case study of a DWL, a RL, and a RL-DWL combination (colored bars on top of (d, e, f)): (a) net heat flux, $Q_{\text{Net}}$, modeled solar heat flux for clear-sky conditions, $Q_{\text{Solar}}$, wind stress, $\tau$, and triangles color-coded by $U_{10}$; (b) $R$ observed locally at the research ship or the max value observed either locally or within the upstream radar sector, $R_{\text{MAX}}$, and the area, $A$, of the radar sector that was filled by rain echoes; (c) 2-m, and 3-m S from Chameleon profiler; (d) $N_S^2$; (e) $N_T^2$; (f) $N_{S+T}^2$. Solid and dashed lines in (d-f) indicate the depth of the stable layer top, $h_S$, and the depth of the stable layer base, $h_B$. 
Figure 3: Observed $N^2$ due to $S$ (a, d), $T$ (b, e), $S$ and $T$ (c, f) as a function of depth and time during two equatorial, central Indian Ocean cruises. The depth of the stable layer, $h_S$, stable layer base, $h_B$, and thermocline, $h_{TC}$, were determined by the total $N^2$ field (c, f). A line marks the depth of $z = 5$ m. The state of the MJO was defined by the RMM index (WH04), which corresponds to suppressed, disturbed, active, and westerly wind burst (WWB) time periods in this study (Table 1, Sec. 2a).
Figure 4: Histograms of observed central Indian Ocean: (a) stable layer depth, $h_S$; (b) stable layer thickness, $h_B - h_S$; (c) thermocline depth, $h_{TC}$, normalized by length of dataset.
Figure 5: Histogram of $U_{10}$ measured during DYNAMO for different 0-5 m ocean stability conditions: all data (grey), when no stable layers were present (i.e. when water was well-mixed from 0-5 m, black), when only DWLs were present (red), when RL-DWL combination layers were present (green), and when only RLs were present (blue).
Figure 6: Time series of observed ocean stable layer depth, $h_S$, colored by stable layer type (a, d); $U_{10}$ and $Q_{\text{Net}}$ (b, e); max $R$ observed within the radar rain sector and the ship gauge, $R_{\text{MAX}}$ (c, f). Yellow horizontal lines denote $U_{10} = 7$ m s$^{-1}$ and $Q_{\text{Net}} = -500$ W m$^{-2}$ in (b, e) and $R_{\text{MAX}} = 5$ mm h$^{-1}$ in (c, f). The state of the MJO was defined by the RMM index ($WH04$), which corresponds to suppressed, disturbed, active, and westerly wind burst (WWB) time periods in this study (Table 1, Sec. 2a).
Figure 7: Hourly means of clear sky $Q_{\text{Solar}}$, $Q_{\text{Net}}$, $U_{10}$, $R_{\text{MAX}}$ (a) repeated in both top panels for reference. Hourly likelihood of stable layer existence (b, e, h, k), counts of stable layer start times (c, f, i, l); counts of stable layer durations (d, g, j, m), of all RLs, all DWLs, RL-DWL combinations, and all continuous stable layers regardless of type. The RL and DWL categories include instances of RL-DWLs, in which RLs and DWLs overlapped. The “all continuous stable layer” category in (k, l, m) considers a time period in which multiple stable layers occurred as one event, so the upper panels do not add to the bottom panel. Top panels: mean diurnal cycles of clear-sky $Q_{\text{Solar}}$, $Q_{\text{Net}}$, $U_{10}$, and $R_{\text{MAX}}$. In this study, sunrise = 00:30 UTC (vertical solid line) and sunset = 12:30 UTC (vertical dashed line), which are marked in the $0^{\text{th}}$ and $12^{\text{th}}$ histogram bins.
Figure 8: DYNAMO measured buoyancy flux, $B$, due to heating, cooling, and evaporation by $Q_{\text{Net}}$, $B_Q$, and due to the net effect of rain freshening and rain cooling, $B_R$ (Appendix A). The state of the MJO was defined by the RMM index (WH04), which corresponds to suppressed, disturbed, active, and westerly wind burst (WWB) time periods in this study (Table 1, Sec. 2a).
Figure 9: DYNAMO observed stable layer depth ($h_S$), estimated stable layer depth from surface fluxes ($\hat{h}_S$), mean observed stable layer ($\bar{h}_S$), observed thermocline depth ($h_{TC}$), and monthly-mean mixed layer depths ($h_{1M}$ and $h_{M1}$) for this location in Oct and Nov 2011 according to climatologies by de Boyer Montegut et al. (2004, $h_{M1}$) and Holte et al. (2017, $h_{M2}$). The state of the MJO defined by the RMM index (WH04), which corresponds to suppressed, disturbed, active, and westerly wind burst (WWB) time periods in this study (Table 1, Sec. 2a).
Figure 10: Calculated (a) $u_{W*}^3$ and (b) $\bar{U}_S$ using different stable layer depths of $h_S = 1, 2, \text{ and } 5\ m$ and measured $B$ in [7] and [10]. The value of $\bar{U}_S$ is the highest value of $U_{10}$ at which wind mixing and $B$ should support the existence of a stable layer at depth $h_S$. Examples of $B$ for various net heat fluxes ($Q_{Net}$ abbreviated as $Q$ in plot) and rain rates ($R$) shown atop each plot for reference.
**Figure 11:** Histograms of $Q_{Net}$, $U_{10}$, and $R_{MAX}$ (max $R$ observed within rain sector of Fig. 1) in either the absence or presence of DWLS (a, b) or RLs (c, d) normalized by length of dataset.
Figure A1: Normalized histograms of measured central Indian Ocean buoyancy flux, $B$. Vertical colored lines indicate $B$ for various heat fluxes (negative into the ocean), rain rates, and evaporation.
